

Empirical check on the DR24 test set:

Where control works
 $q = 0.05 \rightarrow \text{realised } 0.057$
 $q = 0.10 \rightarrow 0.090 \cdot q = 0.20 \rightarrow 0.194$

Why it can fail below 5 per cent
coarse p-value grid, and dependence shared by
a common calibration set (realised 0.033 at $q = 0.01$)
